Supporting Information

ABSTRACT: We evaluate the effect of epoxy surface structuring on the evaporation of water droplets containing *Staphylococcus epidermidis*. During evaporation, droplets with *S. epidermidis* cells yield to complex wetting patterns such as the zipping-wetting and coffee-stain effects. Depending on the height of the microstructure, the wetting fronts propagate circularly or in a stepwise manner, leading to the formation of octagonal or square-shaped deposition patterns. We observed that the shape of the dried droplets has considerable influence on the local spatial distribution of *S. epidermidis* deposited between micropillars. These changes are attributed to an unexplored interplay between the zipping-wetting and the coffee-stain effects in polygonally shaped droplets containing *S. epidermidis*. Induced capillary flows during evaporation of *S. epidermidis* are modeled with polystyrene particles. Bacterial viability measurements for *S. epidermidis* show high viability of planktonic cells, but low biomass deposition on the microstructured surfaces. Our findings provide insights into design criteria for the development of microstructured surfaces on which bacterial propagation could be controlled, limiting the use of biocides.

1. INTRODUCTION

The production of biological and chemical materials that control the growth and survival rate of microorganisms at surfaces is of great interest for future antimicrobial strategies. An important factor affecting the development of bacterial colonies is the initial adhesion to the surface, which initiates proliferation and biofilm formation and has major impact in contamination of medical devices. For example, *Staphylococcus epidermidis* infections can commence with the introduction of bacteria transferred from the skin during medical device insertion, and account for at least 22% of bloodstream infections in intensive care unit patients. It has recently been found that a surface with micro(nano)-topography in contact with microorganisms can influence microbial growth, attachment, and distribution. In addition, modifying surface topography can also create water repellent substrates, which may prevent infections by reducing bacterial growth and propagation after the evaporation of the liquid. However, droplets in such superhydrophobic or hydrophobic states are energetically unstable and eventually the droplet gets impaled by the microscopic structure, losing the hydrophobic character and causing the liquid to infiltrate the structure. Such a transition can however be avoided by suitable engineered micropatterned substrates with sharpened pillars or with relatively high microstructures. In addition, the spreading of the liquid front is also affected by the pillar geometry, leading to a droplet footprint with a polygonal shape. This phenomenon has been termed zipping-wetting and it has been observed for submillimetric structures. As well as forming elaborately patterned footprints on surfaces, the dried pattern can have profound effect on the distribution and survival rate of bacteria on a substrate. However, little is known about how the presence of bacteria in droplets affects the drying on microstructured surfaces and how the bacterial interaction at the wetting front affects the resulting bacterial deposition over the substrate. This problem can be compared to the behavior of particle suspension droplets, which, upon evaporation, have been shown to leave distinct patterns.

2. METHODS

2.1. Deep Reactive-Ion Etching of Silicon. Photolithographically defined silicon micropillar arrays were produced with deep reactive ion beam etching (DRIE) as described in detail elsewhere. In a DRIE system (Adixen AMS100-SE), with a RF generator at 13.56 MHz, CCP 80 W LF, and 1500 W ICP plasma source, the micropillar arrays were etched by keeping the total chamber pressure at 75 mTorr. The temperature of the electrode with the silicon substrate was kept at 250 sccm (standard cubic centimeter per minute), 30°C, using liquid nitrogen as a coolant. The etching time was varied from 5 to 15 min and isopropanol, dried, and treated in air plasma for 1 min in a Femto Diener plasma cleaner (Zepto model).

2.2. Fabrication of Polydimethylsiloxane (PDMS) Molds. Epoxy micropillars were produced by casting EPO-TEK (OG142–13 from Epoxy Technology) onto the negative PDMS replica described in subsection 2.2. After PDMS was cast, a glass slide was placed over the PDMS substrate with epoxy material. The epoxy was cured using ultraviolet light. A UVL-S6 hand-held UV lamp was used (6 W and wavelength of 365 nm) for 30 min followed by incubation at 30 °C for 30 s.

2.4. Configuration of Micropillars on Epoxy Substrates. Epoxy micropillars were fabricated by casting and curing epoxy glue on a negative PDMS micropillar- replica as described in subsection 2.3. These microstructures, labeled from (a) to (c), are shown in Figure 1. The diameter (d) and inter spacing (i) were restricted in the range presented in Table 1, but the heights (h) were varied from 5 to 15 μm.

Table 1. Height (h), Pillar-to-Pillar Interspace (i), and Diameter (d) of the Microstructures on Substrates (a)–(c)

The configuration of the microstructures is in a square lattice with a periodicity p = i + d with a packing fraction Θ, calculated as (π/4)(d/p)^2 of about 0.19 and aspect ratios (h/d) of approximately 1, 2, and 3 for (a), (b), and (c), respectively. The outside walls of the micropillars are smooth at the micrometer scale for all of the substrates.

2.5. Determination of S. epidermidis Cell Viability after Evaporation of Bacterial Suspension over Structured Surfaces. S. epidermidis (ATTC-12228) cultures were grown overnight (200 rpm, at 37 °C) in nutrient broth (NB) medium (Oxoid, Ltd.-Thermo Fisher). The bacterial cells were adjusted to 6.3 × 10^7, 8.0 × 10^7, and 5.0 × 10^8 colony forming units per milliliter (CFU/mL) in sterile deionized water.

S. epidermidis viability was carried out with flat and structured epoxy micropillar substrates sterilized under UV light for 20 min. Here 10 μL of droplets of fresh bacterial cell suspension (9 × 10^7 CFU/mL in water) were deposited onto H5, H10, H15, and flat substrates sterilized under UV light for 20 min. Complete evaporation, each substrate was rehydrated in 1 mL of NB and the cells were cultured for 24 h at 37 °C. Counting of viable cells was performed after washing the surface with 200 μL of sterile phosphate-buffered saline (PBS) and serial dilutions. The experiments were performed in triplicate.
The biofilms formed were stained with 500 μL of a 0.1% crystal violet for 15 min at room temperature (RT). Crystal violet was removed; materials were washed 5 times with sterile water and dried. For quantification of biofilms formed on the flat and structured substrates, 500 μL of absolute ethanol was added (for 15 min at RT) to solubilize the stain and transferred to a new plate. The optical density (O.D.) 959 nm was measured in a UV/vis plate reader (FilterMax F5Multi Mode Microplate Reader, Molecular Devices). Three independent experiments were performed.

2.7. Contact Angle Measurements on Epoxy Micropillar Arrays. Contact angle measurements were performed by placing a water droplet of 2–4 μL on the epoxy substrates with the setup presented in Figure SI-1. Evaporation occurred at room temperature (21° ± 3 °C) in an atmosphere with a relative humidity of 35 ± 5%. The water was purified in a Millipore Milli-Q system which involves reverse osmosis, ion-exchange, and filtration steps (18.6 MΩ cm).

Side-view videos were captured via a CMOS camera equipped with x5- x40 magnifying lenses and with a recording time of 1–2 fps. Contact angle measurements of water and *S. epidermidis* droplets on epoxy surfaces were carried out by placing a water droplet with bacteria suspension of 6.3 × 10^6, 8.0 × 10^6, and 5.0 × 10^6 CFU/mL on the epoxy substrates. After deposition, the droplets evaporated at room temperature. Top-view droplet evaporation images were recorded at frame rates of 10 fps with a camera (Photron Fastcam SA7) with a 1200 s exposure time are shown in Figure SI-2. Contact angle (CA) measurements as a function of time are shown in Figure SI-2.

2.8. Deposition of Polyamide Tetras on Epoxy Substrates. A 10^-7 particles/mL solution of FluorRed-polyamide (PS) particles purchased from MicroParticles GmbH with mean diameter of 1.2 μm ± 0.04 μm was prepared with deionized water (Milli-Q). Drops of 2–4 μL were deposited on the epoxy substrates. Substrate inspection was performed with an inverted microscope illuminated with a continuous solid-state laser diode pumped at 100 mW (or a halogen light) to avoid overheating. The images were collected with a CCD camera PCO Sensicam at 1 frames per second (fps). The droplets were evaporated at 23 °C and 40% relative humidity. Under such conditions, 2–4 μL droplets evaporate completely in approximately 1200 s ± 250 s. Contact angle (CA) measurements as a function of time are shown in Figure SI-2.

2.9. SEM and AFM Characterization. Fracturing the epoxy/glass substrates with a diamond cutter, a cross-sectional scanning electron microscope (SEM) image of the fabricated epoxy micropillars was collected with accelerating voltages of 3 kV and ×1300 magnification using a JSM-6610 JEOL scanning electron microscope. To increase the electrical conductivity of the micropillars, prior to SEM analysis a 20 nm chromium layer was deposited by sputtering.

Atomic force microscopy (AFM) studies were conducted using Keysights (formerly Agilent) 5500 atomic force microscopy. A droplet of bacteria suspension (8 × 10^6 CFU/mL) as described in subsection 2.7 was applied onto the micropillar substrate and dried at room temperature. Measurements were carried out in air using intermittent contact mode (tapping mode) utilizing uncoated silicon NCHV cantilevers (Bruker, Santa Clara, CA). These cantilevers have typical resonance frequencies of 320 kHz and a typical spring constant of 42 N/m (with a tolerance of 20–80 N/m). Due to the pillar size, the scan rate was set to 0.1 Hz and 5 V amplitude was used for imaging. Height phase-shift images were recorded and line-fitted using PicoView software supplied by Keysights.

### 3. RESULTS AND DISCUSSION

3.1. Substrates Decorated with Micropillar Arrays. We first investigated the wetting and evaporation behavior of water droplets on substrates (Figure SI-1) decorated with a pillar height of 5 μm (H5), 10 μm (H10) and 15 μm (H15). After deposition, the wetting transition from Cassie–Baxter state to the Wenzel state was clearly visible for substrates H5, H10, and H15 at t ∼ 80 ± 40 s. On all our samples, the static CA for water was found to be ∼100° (±7°). We measured the CA of the water droplet as a function of time. The dynamics of CA values of water on these fabricated pillars are displayed in Figure SI-2. Initial CA was 98° ± 6°, 105° ± 5°, and 100° ± 7° for H5, H10, and H15, respectively. Hysteresis was 20° ± 5°, 35° ± 8, and 60° ± 15 for H5, H10, and H15, respectively. High hysteresis is expected for wetted surfaces H5, H10 and H15. This caused by a loss on hydrophobicity followed by droplet impalement in the micropillars. High hysteresis values have also been observed for polymeric substrates. It has been reported that capillary forces applied by sessile droplets can deform elastic surfaces. This explains the strong hysteresis we observe for H15 surfaces in Figure SI-4c and f.

During evaporation, the CA of the droplets decreases (Figure SI-2), zipping-wetting propagation is observed (shown in Figure SI-5 between t = 800 and 930 s), which has also been observed for comparable configurations. In the previous studies, the zipping-wetting effect was observed with the propagation of the fluid entering and filling the microstructures as seen in Figure SI-5. The zipping-wetting process of these droplets is energetically favored at low CA (e.g., t = 650 s, see Figures SI-2 and SI-5), and it becomes more favorable for the higher pillars.

3.2. Evaporation of *S. epidermidis* Suspension over Substrates with Micropillars. In order to investigate the behavior of droplets containing bacteria, three different concentrations of *S. epidermidis* suspensions (6.3 × 10^6, 8.0 × 10^6, and 5.0 × 10^6 CFU/mL) were prepared as described in subsection 2.5. The pattern of bacterial distribution after drying is affected by both the concentration of *S. epidermidis* in the water droplets, and the height of the pillars as presented in Figure 2. A homogeneous bacterial distribution is observed for (a) H5, (b) H10, and (c) H15 at the high concentration of 5 × 10^6 CFU/ml.
bacteria (5.0 × 10^9 CFU/mL). We hypothesize that this cell distribution is governed by a high amount of *S. epidermidis* agglomerates at the last moment of evaporation. A microbial adherence test to n-hexadecane was performed to estimate *S. epidermidis* hydrophobicity. This technique has been used to qualitatively estimate surface hydrophobicity of cells.

---

Figure 4. (a) Sketch of drying patterns of evaporated droplets with *S. epidermidis* between micropillar troughs. From left to right: completely filled structure, square lattice with empty central space, bacteria in “C” shape, bacteria in “L” shape, and “I” single line of bacteria. (b) Representative bright field modular microscope image of an evaporated droplet area over H5 containing *S. epidermidis* patterns. Highlights represent a bacterial environment for each category identified by color in (a,b). (c) Chart of the percentage of *S. epidermidis* patterns deposited in H5, H10, and H15. (d) Count number of viable *S. epidermidis* cells recovered after 24 h after rehydration on flat surface and on substrates decorated with micropillars H3, H10, and H15. Experiments in (c) were performed in triplicates by drying 10–20 independent droplets over substrates. The number of pattern in (c) was estimated from five entire evaporated droplets per dried substrate. Microbiological test in (d) were carried out independently in triplicates. Values in (c) and (d) are expressed ± SD.
Cellular interactions are assumed to be subjected to forces similar to those governing colloidal aggregations between surfaces or particles in liquid. The hydrophobic interaction forces are strongly attractive and are determined by the amount of hydrophobic/hydrophilic molecular components on S. epidermidis (e.g., polysaccharides or hydrophobins). From our experiments, cultured S. epidermidis cells reveal hydrophobicity of 58% ± 5%. This suggests that attractive forces between hydrophobic cells interact stronger via van der Waals forces which could promote agglomeration leading to aggregates during evaporation.

As the concentration is reduced to $6.3 \times 10^6$ CFU/mL, the classical ring-shaped stain is not visible using only white light due to the reduced amount of bacteria. Only few bacterial clusters at the border of the stain are observed in Figure 2a−c. Moreover, for the intermediate concentration ($8.0 \times 10^7$ CFU/mL) an accumulation of bacteria in the center of the octagonal shape was observed alongside bacterial distribution at the borders (Figure 2b). This implies that the final evaporation patterns depend on a sensitive balance between bacteria and capillary interactions during the final stages of evaporation. It is important to note that in the current conditions Marangoni flow is much smaller than the dominant evaporation-driven flow.

The zipping-wetting effect was also observed for S. epidermidis containing droplets. Figure 3 shows a top-view image of a droplet containing S. epidermidis deposited over H15. An irregular octagon was observed until $t \sim 700$ s, after which the droplet changes into a square shape, as the fluid fills the cavities between the micropillars. It is observed that at $t = 960$ s, the liquid spread out from the corners of the droplet with the formation of a cross structure stretching outside the square pattern at $t = 1120$ s. Similar effects were also observed for evaporating droplets with higher bacterial concentration (e.g., $5.0 \times 10^7$ CFU/mL); see the Supporting Information videos with H15.

To evaluate both, the zipping-wetting and the coffee stain effects during evaporation of droplets containing S. epidermidis, we studied the distribution of the localized bacterial patterns as well as bacterial cells viability. An intermediate bacterial concentration of $\sim 8.0 \times 10^7$ CFU/mL was chosen for the work in the following sections as this gave a clear visualization of the dried bacterial patterns (Figure 2).

### 3.3. Localized S. epidermidis Deposition Environments between Micropillars

We investigated the localized environment of the bacteria within the troughs of the micropillars after evaporation using the entire droplet area (i.e., droplet perimeter and center of the droplet). Figure 4a shows a top-view illustration of a square lattice composed by four micropillars (gray dots) with bacteria (red dots) in the troughs. Different local bacterial environments between pillars are depicted as follows: a completely filled structure (red box); a square lattice with four filled edges and an empty central space, “O” shape (green box); a three sided deposition with bacteria in “C” shape (purple box); a two sided “L” shape bacterial distribution (blue box); and, finally, a single line (”I”) of bacteria (pink box). A top-view bright field modular microscope image of a micro-patterned substrate with deposited S. epidermidis is shown in Figure 4b highlighting the different kinds of local environments that are experimentally observed for the bacteria. It can be seen that all five environments are observed, highlighted with an arrow of the same color as used in Figure 4a. In contrast to the structured surfaces, flat epoxy surfaces do not contain similar well-defined localized bacterial configurations. For comparison, a representative image of dried bacteria patterns on a flat epoxy surface is presented in Figure S1-7.

To establish the detailed distribution of bacteria suggested from the light microscope data, AFM images were collected. Due to limitation of the depth that can be probed by the AFM, imaging was only used to identify the deposition of the bacteria on substrate H5 (Figure 1a). The AFM data in Figure S shows that a high proportion of S. epidermidis cells were found at the bottom of the troughs in the space between pillars and a significantly smaller population of bacteria was found on top of the pillars. AFM images were processed to enhance the contrast between the floor (purple color), deposited bacteria (light blue colors), and top of pillars (red color).

The AFM image in Figure 5 clearly shows that the deposition shapes observed by light microscopy in Figure 4b. This can be directly attributed to the local environment and deposition pattern of the bacteria (Figure 2a). We have therefore mapped the statistical distribution of the different local environments of the deposited bacteria as the pillar height of the substrate is changed (shown in Figure 4c). It can be seen that the H5 and H10 distribution is comparable, with a similar distribution for the “O”, “C”, and “L” environments (each approximately 15% of the total number of patterns). In contrast, the H15 has a much higher concentration of completely filled troughs and much fewer low-concentration local environments. H5 and H15 show opposite behavior, with the taller substrate forming high concentrations of local environments and vice versa, while H10 can be considered an intermediate case. Therefore, the discussion is focused on substrates H5 and H15. Note that.

**Figure S.** 3D-AFM image of a H5 surface with S. epidermidis patterns deposited at the bottom of the troughs and atop of pillars. Patterns formed by S. epidermidis are highlighted with colored arrows as shown in Figure 4a and b. Note that, from the 3D-AFM image, the lower plane between the micropillars troughs is purple and bacteria on the floor of the surface are in blue colors.
Figure 6. (a) Biofilm formation assay with S. epidermidis cultured for 24 h over surfaces: polystyrene flat (PSflat), flat epoxy (flat), H5, H10, and H15. (b) Normalized biofilm mass to ERI for PSflat, flat, H5, H10, and H15. Three independent experiments were performed. All values are expressed ± SD.

proportion of localized S. epidermidis environments shown in Figure 4c are collected from three independent experiments using the entire area of five dried droplets.

For H5 in Figure 4c, the highest proportion of the bacterial environments were found for clusters in “I” shaped environments (ca. 33% of deposition environments), whereas for H15, a 7-fold decrease in the proportion of “I” shaped environments is observed. Moreover, there is an increase in the proportion of totally filled “O” shaped local environments seen for the H15 substrate when compared to H5 substrates (37% of the total number of environments for H15 compared to 14% for H5). These results confirm that the induced bacterial deposition environments can be tuned by changing the pillar heights. We suggest that the observed distribution of S. epidermidis in Figure 4c can be associated with capillary flow of the evaporated droplets. Thokchom et al. have reported that motile and nonmotile cells can be directed with the formation of ring deposits on uncoated substrates. Moreover, S. epidermidis preferential cell attachment to the lower areas between pillar troughs has also been reported and we confirm here this observation. This implies that our localized bacterial environments are actively driven by the flow during evaporation and not by the nonmotile microorganism. It is important to mention that S. epidermidis configurations may also vary in their size and shape adapting to the configuration of the decorated surface.

To assess how the local environment affects bacterial growth, bacterial viability of planktonic cells after rehydration was measured and is shown in Figure 4d. H5 shows slight bacterial growth inhibition compared to flat, H10, and H15 substrates. We hypothesize that H5 sample contains a larger proportion of smaller local environments which could be more vulnerable to dehydration and cell death when compared to the larger local environments which are more prevalent on the H15 sample.

Biofilm formation assays were performed for S. epidermidis deposited over surfaces. This method provides additional insights on the antibacterial performance of structured materials by estimating the bacterial biomass formed on surfaces. Here, polystyrene flat surface (PSflat), flat epoxy surface (Flat), and H5, H10, and H15 epoxy substrates were used. In Figure 6a, we present optical density (OD) values. Representative images of a well plate for each surface are also presented. Images were recorded after crystal violet staining for PSflat, flat, H5, H10, and H15. High levels of S. epidermidis biofilm mass are found for the PSflat substrate with an OD ~ 0.45. A substantial reduction of biofilm mass is obtained for flat, H5, H10, and H15 epoxy substrates. The lowest OD values are ~0.12 for flat and H5, while those for H10 and H15 are 0.17 and 0.25, respectively. From our biofilm mass optical density assay, measured as intensity reduction of a light beam transmitted through the biofilm, we have correlate the formed biofilm mass, measured as total carbon and as cell mass. Biofilm formation assay shows clearly the importance of both chemical composition of the material and surface topography. It has been demonstrated that staphylococci show great versatility to adhere to polymers, like polystyrene materials. Thus, when compared to PSflat substrate (i.e., highest biofilm mass), epoxy surfaces reveal promising material properties which could reduce biofilm mass deposition. Interestingly, in spite of high S. epidermidis viability in planktonic state (Figure 4d), biofilm formation over epoxy surfaces is relatively impaired. It is clear that S. epidermidis viability can only be affected by the surface topography since no additional surface functionalization was performed. High levels of viable cells have also been observed for functionalized and nonfunctionalized surfaces, whereas the topographic surface remains with fewer bacterial cells.

To assess the effect of surface topography and its ability to reduce S. epidermidis attachment, biofilm mass values from Figure 6a were normalized to the engineered roughness index (ERI) in Figure 6b. ERI (i.e., ERI = (r × df)/f0) is a dimensionless value used to characterize surfaces with engineered topographies which solely considers the micro-pillar geometry, the spatial arrangement of the microstructured substrate, and the size of the topographical features. ERI equation comprises of three parameters, the Wenzel’s roughness factor (r) which is defined as the ratio of the actual surface area to the projected planar surface area, the depressed surface fraction (f0), as the ratio of the recessed surface area between the protruded features and the projected planar surface area, and the degree of freedom of movement of the microorganism of the recessed areas (df). This ERI equation shows that PSflat substrate has the highest normalized biofilm mass. Compared to flat surface, PSflat has ~75% more formed biofilm mass.
biofilm mass. Moreover, H5, H10, and H15 substrates show an ∼50% reduction in normalized biofilm mass compared to flat epoxy substrate. From the results in Figure 6b, no significant differences are observed between H5, H10, and H15. However, S. epidermidis attachment to H5, H10 and H15, is observed to be reduced when normalized to the geometrical features of the fabricated substrates. Similar trends have been also achieved when O.D. is normalized to total surface area for H5, H10, and H15. From ERI analysis, beyond a quantitative assessment, we have obtained understanding of cell-feature interaction which highlights the importance of the topography on cell attachment.

Two approaches have been used to estimate the antibacterial properties of surfaces. For evaporated droplets, a small decrease in H5 bacterial viability is observed after rehydration and planktonic cell colony counting (Figure 4d). Compared to PSflat, low level of biofilm formed on epoxy substrates is observed in Figure 6a. These results show that, regardless of surface geometry, epoxy surfaces like flat and H5 have promising antibacterial performance. For future geometrical designs, H5 substrate has shown the most desirable antibacterial properties capable of reducing bacterial regrowth (Figure 4d) and bacterial biomass formation (Figure 6a).

3.4. Drying of Droplets with PS Particles. The bacterial patterns described in previous sections correspond to the last stage of the deposition process. In order to understand better such deposition patterns, we perform experiments with PS particles with a mean diameter of 1.2 μm ± 0.04 μm which is comparable to S. epidermidis cell diameter (0.5 to 1.5 μm). The fluorescent labeling of the PS particles allows us to observe how the deposition occurs during the evaporation process.

Experiments are performed on substrates H5, H10, and H15. PS particles concentration was 10^7 particles/mL, which is comparable to the intermediate concentrations used for S. epidermidis in subsection 3.3. First instants of the droplet lifetime are dominated by the zipping-wetting effect, i.e., the contact line spreads in a stepwise manner through the pillars (e.g., Figure SI-5). As a consequence of this phenomenon, the droplet perimeter adopts a polygonal shape. As the pillar height increases from H5 to H15, the corners of the droplet footprint become more squared.

In the last step of the evaporation process, PS particles motion is clearly visible (see Supporting Information videos). PS particles flow is directed toward the droplet corners. The flow rates increase as the corners of the droplet contact line become sharper. Surface H5 shows the lowest amount of PS particles deposits at corners of the droplet perimeter (Figure 7a), whereas a higher concentration of PS particles was seen for the H15 substrate (Figure 7c).

Figure 7a–c is taken from the PS particles in the Supporting Information videos at the last moment of evaporation for H5, H10, and H15 substrate, respectively. The PS particles tend to accumulate in rounded corners close to the contact line as in the H5 (Figure 7a) with a fewer PS particles accumulating in the sharper corners for H10 and H15 (Figure 7b and c). Note that the flow is so strong that in the case of Figure 7b and c the contact line is stretched beyond its pinning position. Due to the enhanced flow toward the corners, those particles that do not reach the contact line are distributed along the surface forming an “X-shape”. This illustrated in Figure 7d.

To quantify the surprising correlation found between the particle accumulation at the corners and the micropillar height, we measure the fluorescent light intensity emitted by the PS particles at different locations of the droplet at different time points during evaporation. The aim is to quantify the particle enrichment at the droplet corners and the depletion at its sides through the fluorescence light intensity, which is directly proportional to the amount of particles. Note that the measurements start at 80% of the total evaporation time. At this time the coffee-stain effect has already able to drag a large amount of particles to the contact line. Therefore, all intensity profiles show a sharp increase as r/R approaches 1 (with r the distance to the contact line and R the droplet radius), i.e., as we reach the droplet’s contact line. If we focus on our attention first on the droplet side perimeter, in Figure 8a and c, we see that, in both cases (droplets in H5 and H15, respectively), there is a clear decrease of the light intensity as the time reaches the final evaporation time (a 50% decrease in H5 and about 75% decrease in H15). This means that particles are being “removed” from the side of the droplet as the solvent evaporates. Now we focus on the fluorescent intensity change at the corners of the droplets in Figure 8b and c for droplets on H5 and H15, respectively. Here, we clearly observe an opposite effect: the fluorescence intensity increases in almost 100% from the first time point measured. This intensity increase at the corners is due to the particle enrichment in the formed polygonal droplets. Note that despite the sharper corners in H15 (Figure 8d), the increase in intensity is comparable to the H5 case (Figure 8b). This is attributed to a large amount of particles in the H15 traveling beyond the pinning line and go beyond the measurement area (shown in Figure 7c).

3.5. Interpretation of the Experimental Results and Physical Explanation. In previous sections, we have shown a clear correlation between the accumulation of particles and bacteria at the corners of polygonal droplets. Additionally,
surfaces with taller pillars show a larger deposits accumulating at the corners.

In the first time point measured after droplet deposition on the substrate, the droplet experiences a wetting transition from a Cassie–Baxter state to a lower-energy Wenzel state by filling the interspace between the micropillars. Under special geometric conditions and solvents, the liquid front advances through the pillar array in a stepwise manner known as zipping-wetting, that gives the polygonal shape to the droplet’s perimeter. It is well-known that surfaces with taller micropillars present sharper corners.\textsuperscript{1−3} The reason is connected with the smaller curvature that the liquid menisci are able to adopt when the pillars are higher. The contact line remains pinned for practically entire process.

In sessile droplets, the evaporation occurs preferentially at the contact line\textsuperscript{6} and consequently a capillary flow develops and transports liquid and particles to the droplet’s perimeter. Such flow drags the particles or bacteria toward the perimeter, explaining the high fraction found at the borders of the droplet. This phenomenon, known as the “coffee-stain effect” explains the ring-shaped stains formed by the evaporation of a suspension droplet on flat substrates.

The evaporative flux ($J$) at the droplet’s surface depends on the distance from the contact line $r$. For the case of very thin droplets, the flux takes the form $J(r) \sim DC_s/R(r/R)^{-0.5}$, where $D$ is the vapor diffusivity, $C_s$ is the vapor concentration difference, $R$ is the droplet radius, and $r$ is a radial distance from the contact line.

The evaporation process changes dramatically when the contact line curves develop “angular regions” as described by Popov and Witten.\textsuperscript{61} They analyzed an idealized case of a perfectly sharp corner (curvature radius $R_c = 0$ in Scheme 1). They demonstrated analytically that the evaporative flux near an angular region is strongly enhanced with respect to a straight contact line. This is expressed as $J \sim DC_s/R_c(r/R_c)^{-0.7}$ for an angular wedge of angle $\alpha = 90^\circ$. Here, we estimate the outer length scale to be the size of the drop. Therefore, a particle in an evaporating square-shaped droplet feels a preferential flow toward the corners (see Figure 8). The angular region at the corner of the droplet is smoothened on a scale $r \sim R_c$, i.e., the curvature is not apparent when one sits very close to the corner.

At such a scale, we should recover the square root behavior $J \sim DC_s/R_c(r/R_c)^{-0.5}$, but now with $R_c$ as the relevant scale.

Assuming that the flow velocity is directly proportional to the evaporative flux $J$, we compare the flow toward the corners

**Figure 8.** Fluorescent light intensity emitted by PS particles. The intensity is proportional to the particle density. Measurements in (a, c) and (b, d) were performed during drying of a droplet over substrate H5 and H15, respectively. (a, c) Intensity change from the center to the side perimeter of the droplet; (b, d) intensity change from the center of the droplet to the corner. Intensity measurements are presented during last intervals before complete evaporation, e.g., 80% (black line), 90% (red line), and 98% (blue line).

inhomogeneous deposition of particles along the droplets metric evaporation process is found to be responsible for the deposition patterns are achieved by changing the pillar height of pillared substrates was studied. Variations in the shape of the pillars have typical diameters of 5 μm, while the droplets have typical radius, R, of 1 mm.

4. CONCLUSIONS

The evaporation of induced bacterial patterns over micro-pillared substrates was studied. Variations in the shape of the deposition patterns are achieved by changing the pillar height of the fabricated micropatterns. We show that the nonaxisymmetric evaporation process is found to be responsible for the inhomogeneous deposition of particles along the droplets perimeter. This is a result of the combined action of the coffee-stain effect and the zipping-wetting effect which results in the breakdown of symmetry of the perimeter of the droplet. Variations in bacterial distribution are explained by the enhanced evaporation-induced flow toward the corners of the polygonal droplets on the substrates. We observed a sharp difference in the type of local environment, as the pillar height is increased. The H15 substrates induce the deposition of bacteria into environments with high local concentration of cells. On the other hand, on the smaller pillar heights, a lower local concentration environment is favored. Our results indicate that low height microstructured surfaces can lower bacterial regrowth and biomass attachment. These findings could be utilized for the design of novel topographical antimicrobial surfaces.
