### Key Points

- Jet flow over a foredune is examined for a range of wind speeds/directions.
- Jets develop regardless of wind speed, best developed for perpendicular winds.
- Surface roughness affects jet development

### Abstract

Jet flows, which are localized flows exhibiting a high speed maxima, are relatively common in nature, and in many devices. They have only been occasionally observed on dunes, and their dynamics are poorly known. This paper examines computational fluid dynamic (CFD) 2D modelling of jet flow over a foredune topography. Flow was simulated in 10° increments from onshore (0°) to highly oblique alongshore (70°) incident wind approach angles. CFD modelling reveals that the formation of a jet is not dependent on a critical wind speed, and an increase in incident wind velocity does not affect the magnitude of jet flow. A jet is first formed at ~1.0m seawards of the foredune crest on the Prince Edward Island foredune morphology example examined here. A jet is not developed when the incident wind is from an oblique approach angle greater than ~50° because there is significantly less flow acceleration across a much lower slope at this incident angle. The presence of a scarp does influence the structure of the crest jet, in that the jet is more pronounced where a scarp is present. Surface roughness affects the magnitude of jet expansion and jets are better developed on bare surfaces compared to vegetated ones.

**Keywords:** Foredune, jet, jet flow, computational fluid dynamics (CFD), flow dynamics; .

### 1. Introduction

Jet flows are relatively common in nature, and in many devices. A jet is a localized flow exhibiting a high-speed maxima according to Wei et al. (2013). The word comes from the French *jeter* and Latin *jactare* ‘to throw’, and by the 16<sup>th</sup> Century was used as a verb meaning ‘to jut out’ (<http://www.oxforddictionaries.com/definition/english/jet>), hence the observation

1  
2  
3 that a jet has a well-defined 'nose' in the velocity profile (Wei et al., 2013; see e.g.  
4 <http://www.eng.fsu.edu/~shih/succeed/jet/jet.htm>). Jets may be formed where fluids are  
5 compressed and ejected from nozzles, pipes, taps, engines, exhausts (often as buoyant  
6 plumes) and similar objects or devices (Schlichting, 1955; Birkhoff and Zarantonello, 1957;  
7 Cala et al., 2006). One classic commonly cited example is the flow from a household tap. Jets  
8 are found, or occur in the atmosphere, for example, as low level jets during certain wind  
9 conditions (e.g. Kraus et al., 1985; Brook, 1985), as coastal phenomena associated with  
10 temperature gradients (e.g. Parish, 2000), in wakes behind bluff bodies (Bickley, 1939;  
11 Mattingly and Criminale, 1972), in various marine animals such as sponges and mollusks  
12 (Vogel, 1996), in tidal flows (e.g. Joshi, 1982), in river mouths and streams (e.g.  
13 Abramovich, 1963; Wright, 1977, Allen, 1982; Rowland et al., 2009), over stones in streams  
14 (Moth Iversen et al., 1989), in rip currents (e.g. Sonu, 1972, fig 9; Haller and Dalrymple,  
15 2001), over steep slopes, scarps and cliff tops (Bowen and Lindley, 1977; Liu et al., 1999),  
16 and collimated jets are an important ingredient in the formation of stars (Bacciotti et al.,  
17 2003). Brook (1985) stated that "there are many types, their only common factor being a  
18 well-marked maximum in the boundary-layer wind speed profile" (Brook, 1985, p. 133).

In the near-surface terrestrial coastal zone, there have been only a few observations or studies  
of jets within incident flows in blowouts (Hesp and Hyde, 1996) and over dunes and ridges.  
Hsu (1977) measured the existence of a jet just above the surface over the crest of an ice  
ridge, and produced a general model indicating jet flow over similarly shaped dunes and ice  
ridges. Arens (1996), Arens et al. (1995), Petersen et al., (2011), and Hesp et al. (2013) have  
shown that under certain conditions jets occur on, or near the crests of scarps and foredunes.  
These studies demonstrate that sand may be transported across scarps and dune crests due to  
these locally accelerated flows (termed 'jettation' by Arens, (1996) for the suspended sand  
transport component; cf. Petersen et al., (2011)). The occurrence of jets may be related to  
incident wind speed, and/or incident wind direction, since in both the Arens (1996) and Hesp  
et al. (2013) studies, jets only appeared once the incident wind speeds had increased above a  
certain velocity, or approached from a certain wind direction.

In the aeolian/desert literature, jets have been shown to occur near or at the crests of various  
dune types, particularly transverse and barchan dunes, (although in some cases jets are  
observable in the velocity profiles but not discussed). Both Lancaster et al. (1996) and  
Omidyeganeh et al. (2013) have jets in some of their velocity profiles over terrestrial and  
subaqueous barchans respectively. Burkinshaw et al. (1993) encountered marked jets on

occasions at 20-50cm high above the surface at the crest of a 7m high transverse dune. Walker and Shugar (2013, their figure 5a) appear to have a jet present in their dune crest velocity profile for a crest transverse flow. Jets have also been observed over small to large subaqueous dunes (e.g. Bridge and Best, 1988; van der Knaap et al., 1990; Bennett and Best, 1995; Kostaschuk and Villard, 1996).

Since jets are a specific, defined component of the flow field or regime, and may be critical to understanding the general flow behaviour over dunes and other topographies, it is important to recognise these phenomena as a distinct flow region, separate from other components of the flow (e.g. a speed-up region). It is critical to understand jet generation and behaviour over dunes since they may be prevalent more commonly than indicated by the few studies which encountered jets occurring over dunes, and they may be essential in assisting sediment transport up stoss slopes and/or generating onshore or offshore sediment transport downwind of the dune crest (Petersen et al., 2011; Hesp et al., 2013; Bauer et al., 2015). The same jets may be responsible for lifting and/or transporting sediment across vegetation canopies (Hesp et al., 2013), and perhaps in accelerating disturbance events (Hesp and Martinez, 2007). In addition, some models of wind flow over dunes do not consider or generate jets in their development (e.g. Van Boxel et al., 1999).

In the following, we model the development of jets over a foredune topographic profile from Prince Edward Island, Canada, (where jets have been recorded; see Hesp et al., 2009, 2013) via computational fluid dynamic (CFD) modelling, and then examine five principal questions regarding jets over foredunes:

1. Where and when does a jet form?
2. How does it change with incident flow speed?
3. How does it change with incident wind direction/slope?
4. How does it change over a scarped versus a non-scarped dune?
5. How is it affected by a change in surface roughness?

## 2. Methods

### 2.1 Dune Topography

The surface topography for this study is a foredune which has been studied for some years within the Greenwich Dunes unit of Prince Edward Island National Park on the north-east shore of Prince Edward Island (P.E.I.), Canada (see e.g. Davidson-Arnott et al., 2012; Hesp et

1  
2  
3 al, 2009, 2013, Chapman et al, 2013; Walker et al., 2006, 2009; Bauer et al., 2012, 2015;  
4  
5 Delgado-Fernandez and Davidson-Arnott, 2011).

6  
7 The foredune crest is ~8 to 9 m above mean water level with a steep stoss slope (20°-25°) and  
8 an ENE-WSW crestline orientation. A low-gradient, microtidal (~1 m tidal range), moderate  
9 to high energy intermediate beach with a low-tide width of about 35 m is present on the  
10 seaward side of the dune. At the time of survey the foredune displayed a non-vegetated, 0.7  
11 m high scarp, which later filled in with sand following a significant wind storm (see figure 6  
12 in Hesp et al., 2009). The dune was vegetated by *Ammophila breviligulata*, with plant heights  
13 averaging 0.3 m and spatial density ranging from 2 – 45% based on visual assessments of  
14 percent cover on contiguous transects. The digital elevation model used to produce the dune  
15 surface within the computational domain was generated from 3666 RTK-DGPS points  
16 collected in a 100 m x 150 m area on the foredune at PEI.

## 25 26 **2.2 Computational Fluid Dynamics (CFD) Methodology**

27  
28 Wind flow over the dune surface was simulated using computational fluid dynamics (CFD)  
29 CFD is a numerical method of solving fluid flow using the Navier-Stokes equations and has  
30 been successfully used to simulate flow over a number of coastal dune landforms (Wakes,  
31 2013; Wakes et al., 2010; Smyth et al., 2012; 2013; Hesp et al., 2014; Jackson et al., 2011).  
32 The Navier-Stokes equations can also be solved linearly over dunes (Walmsley and Howard,  
33 1985), with less computational cost than CFD, however this method is only appropriate  
34 where the windward slope is small and the wind flow not affected by near surface jets or flow  
35 separation. Wippermann and Gross (1985), also numerically modelled over a barchan dune  
36 using the mesoscale meteorological model, FITNAH (Flow over Irregular Terrain with  
37 Natural and Anthropogenic Heat Sources). FITNAH is however limited by its finest cell  
38 resolution of 2 m.). Simulations in this study were performed using the open source software  
39 OpenFOAM, which is capable of solving a range of complex fluid flows and also includes  
40 tools for meshing the surface topography and visualising the results. In this case, wind over  
41 the dune was calculated as an incompressible flow using a steady state solver, simpleFoam.  
42 Turbulence was modelled using the Renormalised group (RNG)  $\kappa$ -epsilon method (Yakhot et  
43 al., 1992). This is a turbulence model based on the Reynolds-averaged Navier-Stokes  
44 (RANS) equations, which focuses on the effects of turbulence on the average flow rather than  
45 resolving turbulence at every scale, as with direct numerical simulation (DNS) or at the larger  
46 scale such as a large eddy simulation (LES). The RNG model has been used to accurately  
47 simulate near surface flows over a transverse dune in a wind tunnel (Parsons et al., 2004),  
48 coastal dune complex (Wakes et al., 2010), a complex foredune blowout (Smyth et al., 2012;  
49 2013), and flow over a foredune (Hesp et al., 2015). Joubert et al., (2012) also found that the  
50 original  $\kappa$ -epsilon turbulence model reproduced three-dimensional near surface patterns  
51 around a linear desert dune.

57  
58  
59  
60

All simulations in this study were performed in two-dimensions. This approach was used because in three-dimensions, accurate representation of the change in the slope at the crest of the foredune in the mesh proved problematic as it became overly smoothed. In the two-dimensional simulations any change in slope was accurately recreated in the mesh using a polyline. Ideally flow modelling over the foredune would occur in three dimensions as wind is elliptic in nature as demonstrated by Hesp et al. (2015) who confirmed that incident winds which approach obliquely to the dune toe are deflected toward a more crest-normal orientation across the stoss slope of the foredune.

A mesh independence test was performed by calculating wind flow over 3 meshes of 0.5 m, 0.375 m and 0.25 m resolution. Between each case, wind flow at 30 points between 0.1 m and 3 m above the crest of the foredune changed by <1%. Due to the increased resolution of data points, the 0.25 m horizontal resolution mesh was employed for this study. The horizontal extent of each mesh ranged from 156 m for the 0° transect to 199 m for the 70° transect. In all cases the horizontal resolution of the mesh was 0.25 m and the vertical resolution progressed from 0.1 m at the surface to 1.63 m at the upper boundary located 64 m above the beach surface. Vertical cell size resolution of the mesh was restricted by the maximum dune surface roughness height ( $z_0$ ) of 0.05 m. Each simulation was deemed complete when the residuals for each variable being solved (velocity, pressure, turbulent kinetic energy and energy dissipation) decreased by 4 orders of magnitude.

### 2.2.1 Computational Boundary conditions

In each simulation vertical profiles of wind speed ( $U$ ), turbulent kinetic energy ( $k$ ) and energy dissipation ( $\varepsilon$ ) at the inlet boundary were defined assuming a constant shear velocity ( $u_*$ ) value with height using equations 1, 2 and 3 (Richards and Hoxey, 1993 and Blocken et al., 2006):

$$U(z) = \frac{u_*}{k} \ln\left(\frac{z+z_0}{z_0}\right) \quad (1)$$

$$\kappa(z) = \frac{u_*}{\sqrt{C_\mu}} \quad (2)$$

$$\varepsilon(z) = \frac{u_*^3}{k(z+z_0)} \quad (3)$$

Where  $z$  is the height above the surface,  $k$  is the von Karman constant (0.42),  $z_0$  is the surface roughness length and  $C_\mu$  a constant of 0.09.

To examine how flow dynamics changed with wind speed, simulations were conducted using 4 values of  $u_*$  ranging from a minimum of  $0.24 \text{ m s}^{-1}$  to  $0.60 \text{ m s}^{-1}$  (Table 1). For each simulation a surface surrounding the dune was prescribed a surface roughness constant ( $z_0$ ) of  $0.0005 \text{ m}$ , the equivalent of a sand surface (Bagnold, 1960). To test how jet dynamics change with roughness height, the foredune was prescribed roughness heights equivalent to that of bare sand ( $z_0 \text{ } 0.0005 \text{ m}$  (Bagnold, 1954)), *Ammophila breviligulata* ( $z_0 \text{ } 0.01 \text{ m}$  (Olson, 1958)), and thin grass  $0.5 \text{ m}$  high ( $z_0 \text{ } 0.05 \text{ m}$  (Sutton, 1953)).

Table 1 here. Shear velocities ( $\text{m s}^{-1}$ ) and equivalent wind speeds ( $\text{m s}^{-1}$ ) at  $1 \text{ m}$  above the surface at the inlet of the computational domain for each simulation assuming a  $z_0$  of  $0.0005 \text{ m}$ .

TABLE 1 HERE

### 3. Location of the Jet Formation

Because it is often the case that there are not enough instrumented masts in the field to adequately cover a foredune, it cannot be determined exactly where on the stoss face or near-crest region the jet flow is first formed. Thus, the CFD model was utilized to examine where the jet first forms on the foredune. Figure 2 illustrates seven locations across the upper stoss, crest and lee slope where velocity profiles were modelled in order to examine the first point of jet formation, and its downwind extension past the crest (if it occurs).

fig 2 here

In order to assess this, the wind velocity profiles were modelled at intervals of  $0.25 \text{ m}$  across the P.E.I. foredune from upper stoss position over the crest, and down the lee slope to determine where the jet flow structure was initiated (Figure 2a). The transect utilized was the scarp profile, and a roughness height equivalent to *Ammophila breviligulata* ( $z_0 \text{ } 0.01 \text{ m}$ ) was applied to the foredune slope. Figure 2b demonstrates that the flow progressively accelerates up the stoss slope as observed in many similar dune and ridge studies (e.g. Arens et al., 1995; Finnigan, 2007; Walker et al., 2006, 2009; Bauer et al., 2013; Hesp et al., 2009, 2015). While there is some slight indication of jet formation at  $-1.5 \text{ m}$ , a clear jet is formed at  $1.0 \text{ m}$  seawards of the crest. The flow becomes better defined as a more pronounced speed bulge (or nose) develops at around  $50 \text{ cm}$  above the bed at  $-0.75$  to  $-0.5 \text{ m}$  slope, and is most pronounced at  $-0.25 \text{ m}$  seawards or downslope of the crest (Figure 2b). Note that the crest is itself quite convex and rounded (Figure 2a). The jet shifts upwards (to around  $0.75 \text{ m}$  above the surface) and becomes more bulbous in the profile at  $0.25 \text{ m}$  past the crest. It is likely that

1  
2  
3 the very top of the crest is the point at which lee flow separation begins, and as this develops,  
4 the higher speed jet component of the flow is forced upwards over the separation envelope as  
5 observed in other studies (cf. Hsu, 1977). In addition, the flow tends to sweep upwards across  
6 the crest directed by the steep angle of the stoss slope, so the jet will tend to move upwards in  
7 the profile as it crosses the dune crest. Flow velocities are low near the surface in the lee of  
8 the dune crest due to flow separation development in this region.  
9  
10

11  
12  
13 The wind velocity profile with embedded jet at the dune crest displays a similar structure to  
14 that encountered in the field at P.E.I. (Hesp et al., 2009, 2013), and provides partial validation  
15 of the modelling. The vertical height above the bed at which the jet is most pronounced (the  
16 apex of the nose) in the modelling is lower by approximately 50cm (at the crest) to 25cm  
17 (just downwind of the crest) than that encountered in the field. This is likely due to the  
18 presence of vegetation in the field, whereas there is no vegetation present on the modelled  
19 surface.

#### 25 26 **4. Jet Structure and Incident Wind Speed** 27

28 As noted in the introduction, observations of jets formed during different incident wind  
29 speeds have been made (e.g. Hsu, 1977; Arens et al., 1995; Hesp et al., 2009, 2013), but it is  
30 unclear if variations in incident wind speed actually produce changes in the jet formation or  
31 shape. Figure 3 shows wind velocity profiles simulated via CFD for four quite different  
32 incident wind velocities (5 m s<sup>-1</sup> to 12.5 m s<sup>-1</sup> at 4m above the surface on the beach) for a  
33 directly onshore flow.  
34  
35  
36  
37  
38

39 Fig 3 here  
40

41 Jet flow was produced at the foredune crest for all four wind speeds tested (Figure 3) thereby  
42 indicating that once the flow velocity is above the threshold for sand transport, wind speed is  
43 not a factor determining whether a jet is present or not. Whilst it superficially appears as if  
44 the jet becomes more pronounced as wind speed increases (as in Hesp et al., 2013, their  
45 Figure 6)), when the results are made relative to the incident wind speed on the beach (at 4m  
46 height), all the four percent velocity profiles in Figure 3 virtually overlap, and there is only a  
47 very slight difference apparent indicating that incident wind speed has minimal effect on jet  
48 development.  
49  
50  
51  
52  
53  
54

#### 55 56 **5. Jet Development and Incident Wind Direction** 57 58 59 60

1  
2  
3 Field observations of jets (e.g. Hesp et al., 2013) indicates that the jets vary according to  
4 incident wind direction. In order to test the influence of incident wind direction on jet  
5 development, a range of incident wind approach angles from 10° to 70° (almost perpendicular  
6 to almost dune crest parallel) were examined via the CFD model (Figure 4). Figure 1  
7  
8 illustrates the 2-D topographic profiles for the range of incident winds modelled. These show  
9 the relative slopes that the incident wind would encounter or “see” as it crosses the dune.  
10 Note how the slopes flatten considerably and elongate as the incident wind flow becomes  
11 increasingly oblique to the dune crest.  
12  
13  
14  
15  
16  
17  
18  
19

20 Fig 4 here

21 The incident wind angle/stoss slope has a significant impact on the production of a jet at the  
22 crest. As the incident angle becomes more oblique, making the slope less steep, the jet  
23 becomes slower and less defined until it is not discernable past 50° incident wind approach  
24 angle (Figure 4). In the field Hesp et al. (2013) found that a jet did not develop when the  
25 incident wind was from an angle >55°.  
26  
27  
28  
29

30 In three dimensions, the flow is topographically steered before reaching the dune crest  
31 (Walker et al., 2006; Hesp et al., 2015). This may cause the jet to form at more oblique  
32 incident angles than has been found here.  
33  
34  
35

36 The jet is also more pronounced (i.e. more defined nose) in the vertical profile during winds  
37 that are perpendicular to the crest, likely because the stoss slope is steepest for these incident  
38 winds, and perhaps because of the presence of a more defined separation zone, which starts to  
39 limit the near surface wind speed near or at the crest.  
40  
41  
42  
43

44 Wind speed at the crest also decreases as incident wind direction becomes more oblique (cf.  
45 Walker et al., 2009; Hesp et al., 2015). The degree and magnitude of jet development for  
46 three incident directions (0°, 40° and 70°) may be seen in Figure 5. The red zone indicates a  
47 high speed jet zone or region, and this is most pronounced in perpendicular flows. As the  
48 wind becomes increasingly oblique and the dune profile flattens and lengthens, the red zone  
49 decreases in size and the velocity declines. The degree of speedup also decreases as the  
50 incident flow becomes more oblique as indicated by the speed zones in Figure 5.  
51  
52  
53  
54  
55

56 Fig 5 here  
57  
58  
59  
60

1  
2  
3 Figure 6 displays the maximum jet velocity developed at the foredune crest for each incident  
4 wind direction (Figure 6a), and the percent jet velocity relative to winds at 3m above the dune  
5 crest (Figure 6b). Figure 6c illustrates the log regressions of the vertical profiles of wind  
6 velocity up to 3 m height, and shows that as the incident wind becomes more oblique, the  
7 profile becomes more logarithmic. There are clear relationships between these such that the  
8 maximum jet speed declines as the incident wind direction becomes more oblique to highly  
9 oblique, relative jet velocities are highest compared to flow at 3 m above the foredune crest  
10 for directly onshore flow, and the velocity profiles progressively deviate from logarithmic as  
11 the incident flow becomes less oblique. The latter has clear implications for those wishing to  
12 determine shear stress at the bed from velocity profiles where jets are present. All plots have  
13 very high  $R^2$  values.

## 26 **6. Jet development for varying surface roughness**

27  
28 Figure 7 displays jet development for three surface roughness lengths based on data provided  
29 by Maun (2009) and for the same incident onshore wind velocity. It is apparent that the  
30 greatest jet development occurs for a bare sand surface with a very low roughness, and  
31 decreases with the presence of vegetation. There is less near surface turbulence and less drag  
32 where the surface is smooth ( $z_0$  is close to zero in Figure 7), and therefore a greater degree of  
33 near surface flow acceleration upslope. However, there is little difference between a cover of  
34 *Ammophila breviligulata* and tall thin grass (as defined by Maun, 2009).

## 45 **7. Scarped versus non-scarped foredune topography and jet development**

46  
47 Scarps are very commonly formed on foredunes since they occupy the seaward most position  
48 on the backshore (Carter et al., 1990; Hesp, 2002; Christiansen and Davidson-Arnott, 2004).  
49 In the discussion above, the CFD modelling (and previous field work) was conducted over  
50 the P.E.I. foredune which exhibited a small 0.7m high scarp. Since it is also common for jets  
51 to be formed over the crest of such scarps (Bowen and Lindley, 1977; Hesp et al., 2013), the  
52 presence of the scarp and attendant jet may have a downwind influence on the development  
53 of the foredune crest jet. A 2-D CFD comparison was conducted between the scarped profile  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 and the same profile minus the scarp in order to determine if the scarp has a downwind effect  
4 on flow near the crest. Figure 8 demonstrates that the presence of the 0.7m high scarp does  
5 indeed influence the structure of the crest jet, in that the jet is more pronounced where the  
6 scarp is present. The highest velocities are also slightly closer to the bed. This may occur due  
7 to the scarp jet shedding higher velocity and more turbulent eddies downwind up the  
8 foredune stoss face compared to the situation where the scarp is not present.

**Fig 8 here**

20 The presence of the scarp at the dune toe leads to slightly greater development of the jet on  
21 the foredune ridge crest. The pressure fields were also examined for this comparison and  
22 show that (i) the high pressure zone which develops over the scarp region does not extend as  
23 far downwind across the foredune lower stoss slope compared to the non-scarped foredune,  
24 and, (ii) the low pressure zone over the dune crest is much higher (25%) for the scarped dune  
25 compared to the non-scarped dune.

### 33 **8. Conclusions**

34 The following conclusions can be derived from this study:

- 35 1. CFD modelling has successfully replicated jet flow development at a foredune crest region;
- 36 2. an increase in incident wind velocity does not affect the magnitude of jet flow;
- 37 3. a jet is first formed at ~1.0 m seawards of the foredune crest on the Prince Edward Island  
38 foredune morphology example examined here. The flow becomes better defined as a  
39 more pronounced nose develops at around 50 cm above the bed seawards of the crest,  
40 and is best developed at 0.25 m seawards of the dune crest. The jet shifts upwards and  
41 becomes slightly more bulbous in the profile just landwards or past the foredune crest  
42 and then disappears;
- 43 4. the jet is most pronounced and has the greatest aerial extent when winds are perpendicular  
44 to the foredune crest;
- 45  
46

57  
58  
59  
60

- 1
- 2
- 3 5. in the CFD modelling a jet did not develop a few degrees after an incident wind approach
- 4 angle of 50° because there is significantly less flow acceleration across a much lower
- 5 slope at an incident wind greater than ~55°;
- 6
- 7
- 8 6. the jet is higher in the vertical profile during winds that are more perpendicular to the dune
- 9 crest in the 0° to 30° range of incident winds;
- 10
- 11 7. the degree of surface roughness influences the degree of jet development such that jets
- 12 are better developed when the surface is bare compared to when vegetation is present;
- 13
- 14 8. the presence of a scarp at the dune toe does slightly influence the structure of the crest jet,
- 15 in that the jet is more pronounced where a scarp is present.
- 16
- 17
- 18 9. jets are probably more common over dunes and similar topographies than believed or
- 19 found due to (i) post data collection smoothing of velocity profiles (cf. Frank and
- 20 Kocurek, 1996), or (ii) the fact that many field based wind profiling experiments do not
- 21 have enough instruments stacked at closely spaced heights above the surface to be able
- 22 to detect their presence.
- 23
- 24
- 25
- 26
- 27
- 28

29 Future research aims to examine the relationships between foredune morphology (particularly  
30 height and stoss slope gradient) and jet development, the nature of jet breakdown or  
31 dispersion, the nature of secondary circulation and instabilities in jets (see e.g. Ruith et al  
32 2003; Cala et al 2006), and the dynamics and relationships between jet flow and reversing  
33 vortices within flow separation envelopes at, and past the foredune crest.

### 37 **Acknowledgements**

38 The authors thank the School of the Environment and Faculty of Science and Engineering,  
39 Flinders University for equipment grants to P. H. and post-doctoral funding to T.S., and  
40 support, the Flinders University supercomputer facility, the P.E.I. crew Robin, Ian, Bernie  
41 and Jeff, a grant (1024125) from NSF to P. Hesp, and Æolus for his continued ministry. The  
42 data in this paper are available by contacting the corresponding author.

### Key Points

- Jet flow over a foredune is examined for a range of wind speeds/directions.
- Jets develop regardless of wind speed, best developed for perpendicular winds.
- Surface roughness affects jet development

### Abstract

Jet flows, which are localized flows exhibiting a high speed maxima, are relatively common in nature, and in many devices. They have only been occasionally observed on dunes, and their dynamics are poorly known. This paper examines computational fluid dynamic (CFD) 2D modelling of jet flow over a foredune topography. Flow was simulated in 10° increments from onshore (0°) to highly oblique alongshore (70°) incident wind approach angles. CFD modelling reveals that the formation of a jet is not dependent on a critical wind speed, and an increase in incident wind velocity does not affect the magnitude of jet flow. A jet is first formed at ~1.0m seawards of the foredune crest on the Prince Edward Island foredune morphology example examined here. A jet is not developed when the incident wind is from an oblique approach angle greater than ~50° because there is significantly less flow acceleration across a much lower slope at this incident angle. The presence of a scarp does influence the structure of the crest jet, in that the jet is more pronounced where a scarp is present. Surface roughness affects the magnitude of jet expansion and jets are better developed on bare surfaces compared to vegetated ones.

**Keywords:** Foredune, jet, jet flow, computational fluid dynamics (CFD), flow dynamics; .

### 1. Introduction

Jet flows are relatively common in nature, and in many devices. A jet is a localized flow exhibiting a high-speed maxima according to Wei et al. (2013). The word comes from the French *jeter* and Latin *jactare* 'to throw', and by the 16<sup>th</sup> Century was used as a verb meaning 'to jut out' (<http://www.oxforddictionaries.com/definition/english/jet>), hence the observation

1  
2  
3  
4  
5  
6  
7 that a jet has a well-defined 'nose' in the velocity profile (Wei et al., (2013)); see e.g.  
8 <http://www.eng.fsu.edu/~shih/succeed/jet/jet.htm>). Jets may be formed where fluids are  
9 compressed and ejected from nozzles, pipes, taps, engines, exhausts (often as buoyant  
10 plumes) and similar objects or devices (Schlichting, 1955; Birkhoff and Zarantonello, 1957;  
11 Cala et al., 2006). One classic commonly cited example is the flow from a household tap.  
12 Jets are found, or occur in the atmosphere, for example, as low level jets during certain wind  
13 conditions (e.g. Kraus et al., 1985; Brook, 1985), as coastal phenomena associated with  
14 temperature gradients (e.g. Parish, 2000), in wakes behind bluff bodies (Bickley, 1939;  
15 Mattingly and Criminale, 1972), in various marine animals such as sponges and mollusks  
16 (Vogel, 1996), in tidal flows (e.g. Joshi, 1982), in river mouths and streams (e.g.  
17 Abramovich, 1963; Wright, 1977, Allen, 1982; Rowland et al., 2009), over stones in streams  
18 (Moth Iversen et al., 1989), in rip currents (e.g. Sonu, 1972, fig 9; Haller and Dalrymple,  
19 2001), over steep slopes, scarps and cliff tops (Bowen and Lindley, 1977; Liu et al., 1999),  
20 and collimated jets are an important ingredient in the formation of stars (Bacciotti et al.,  
21 2003). Brook (1985) stated that "there are many types, their only common factor being a  
22 well-marked maximum in the boundary-layer wind speed profile" (Brook, 1985, p. 133).

23  
24  
25  
26  
27  
28  
29  
30  
31 In the near-surface terrestrial coastal zone, there have been only a few observations or studies  
32 of jets within incident flows in blowouts (Hesp and Hyde, 1996) and over dunes and ridges.  
33 Hsu (1977) measured the existence of a jet just above the surface over the crest of an ice  
34 ridge, and produced a general model indicating jet flow over similarly shaped dunes and ice  
35 ridges. Arens (1996), Arens et al. (1995), Petersen et al., (2011), and Hesp et al. (2013)  
36 have shown that under certain conditions jets occur on, or near the crests of scarps and  
37 foredunes. These studies demonstrate that sand may be transported across scarps and dune  
38 crests due to these locally accelerated flows (termed 'jettation' by Arens, (1996) for the  
39 [suspended sand transport component](#); cf. Petersen et al., (2011)). The occurrence of jets  
40 may be related to incident wind speed, and/or incident wind direction, since in both the Arens  
41 (1996) and Hesp et al. (2013) studies, jets only appeared once the incident wind speeds  
42 had increased above a certain velocity, or approached from a certain wind direction.  
43  
44  
45  
46  
47

48  
49 In the aeolian/desert literature, jets have been shown to occur near or at the crests of various  
50 dune types, particularly transverse and barchan dunes, (although in some cases jets are  
51 observable in the velocity profiles but not discussed). Both Lancaster et al. (1996) and  
52 Omidyeganeh et al. (2013) have jets in some of their velocity profiles over terrestrial and  
53 subaqueous barchans respectively. Burkinshaw et al. (1993) encountered marked jets on  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6  
7 occasions at 20-50cm high above the surface at the crest of a 7m high transverse dune.  
8 Walker and Shugar (2013, their figure 5a) appear to have a jet present in their dune crest  
9 velocity profile for a crest transverse flow. Jets have also been observed over small to large  
10 subaqueous dunes (e.g. Bridge and Best, 1988; van der Knaap et al., 1990; Bennett and Best,  
11 1995; Kostaschuk and Villard, 1996).

12  
13  
14 Since jets are a specific, defined component of the flow field or regime, and may be critical to  
15 understanding the general flow behaviour over dunes and other topographies, it is important  
16 to recognise these phenomena as a distinct flow region, separate from other components of  
17 the flow (e.g. a speed-up region). It is critical to understand jet generation and behaviour  
18 over dunes since they may be prevalent more commonly than indicated by the few studies  
19 which encountered ~~jets occurring them in studies~~ over dunes, and they may be essential in  
20 assisting sediment transport up stoss slopes and/or generating onshore or offshore sediment  
21 transport downwind of the dune crest ~~{(Petersen et al., 2011; Hesp et al., 2013; Bauer et al.,~~  
22 ~~2015)}~~. The same jets may be responsible for lifting and/or transporting sediment across  
23 vegetation canopies ~~{(Hesp et al., 2013)}~~, and perhaps in accelerating disturbance events  
24 ~~{(Hesp and Martinez, 2007)}~~. In addition, some models of wind flow over dunes do not  
25 consider or generate jets in their development ~~{(e.g. Van Boxel et al., 1999)}~~.

26  
27  
28  
29  
30  
31  
32 In the following, we model the development of jets over a foredune topographic profile from  
33 Prince Edward Island, Canada, (where jets have been recorded: [see Hesp et al., 2009, 2013](#))  
34 via computational fluid dynamic (CFD) modelling, and then examine five principal questions  
35 regarding jets over foredunes:  
36  
37

- 38 1. Where and when does a jet form?
- 39 2. How does it change with incident flow speed?
- 40 3. How does it change with incident wind direction/slope?
- 41 4. How does it change over a scarped versus a non-scarped dune?
- 42 5. How is it affected by a change in surface roughness?

## 43 2. Methods

### 44 2.1 Dune Topography

45  
46  
47  
48  
49  
50  
51 The surface topography for this study is a foredune which has been studied for some years  
52 within the Greenwich Dunes unit of Prince Edward Island National Park on the north-east  
53 shore of Prince Edward Island (P.E.I.), Canada (see e.g. Davidson-Arnott et al., - 2012; Hesp  
54  
55  
56  
57  
58  
59  
60

et al, 2009, 2013, Chapman et al, 2013; Walker et al., 2006, 2009; Bauer et al., 2012, 2015; Delgado-Fernandez and Davidson-Arnott, 2011).

The foredune crest is ~8 to 9 m above mean water level with a steep stoss slope (20°-25°) and an ENE-WSW crestline orientation. A low-gradient, microtidal (~1 m tidal range), moderate to high energy intermediate beach with a low-tide width of about 35 m is present on the seaward side of the dune. At the time of survey the foredune displayed a non-vegetated, 0.7 m high scarp, which later filled in with sand following a significant wind storm (see figure 6 in Hesp et al., 2009). The dune was vegetated by *Ammophila breviligulata*, with plant heights averaging 0.3 m and spatial density ranging from 2 – 45% based on visual assessments of percent cover on contiguous transects. The digital elevation model used to produce the dune surface within the computational domain was generated from 3666 RTK-DGPS points collected in a 100 m x 150 m area on the foredune at PEI.

**Figure 1.** Digital elevation model of the P.E.I. foredune. Orientation of two topographic profile lines relative to the dune crestline used in the CFD modelling are indicated. Topographic profiles over the P.E.I. foredune from 0° (onshore) to 70° (obliquely alongshore). Note that the profile flattens and broadens considerably as the incident flow swings from perpendicular to highly oblique.

## 2.2 Computational Fluid Dynamics (CFD) Methodology

Wind flow over the dune surface was simulated using computational fluid dynamics (CFD) CFD is a numerical method of solving fluid flow using the Navier-Stokes equations and - CFD has been successfully used to simulate flow over a number of coastal dune landforms (Wakes, 2013; Wakes et al., 2010; Smyth et al., 2012; 2013; Hesp et al., 2014; Jackson et al., 2011). The Navier-Stokes equations can also be solved linearly over dunes (Walmsley and Howard, 1985), with less computational cost than CFD, however this method is only appropriate where the windward slope is small and the wind flow not affected by near surface jets or flow separation. Wippermann and Gross (1985), also numerically modelled over a barchan dune using the mesoscale meteorological model, FITNAH (Flow over Irregular Terrain with Natural and Anthropogenic Heat Sources). FITNAH is however limited by its finest cell resolution of 2 m.) Simulations in this study were performed using the open source software OpenFOAM, which is capable of solving a range of complex fluid flows and also includes tools for meshing the surface topography and visualising the results. In this case, wind over the dune was calculated as an incompressible flow using a steady state solver, simpleFoam. Turbulence was modelled using the Renormalised group (RNG)  $\kappa$ -epsilon method (Yakhot et al., 1992). This is a turbulence model based on the Reynolds-averaged Navier-Stokes (RANS) equations, which focuses on the effects of turbulence on the average flow rather than resolving turbulence at every scale, as with direct numerical simulation (DNS) or at the larger scale such as a large eddy simulation (LES). The RNG model has been used to accurately simulate near surface flows over a transverse dune in a wind tunnel (Parsons et al., 2004), coastal dune complex (Wakes et al., 2010), a complex foredune blowout (Smyth et al., 2012; 2013), and flow over a foredune (Hesp et al., 2015). Joubert et al., (2012) also found that the original  $\kappa$ -epsilon turbulence model reproduced three-dimensional near surface patterns around a linear desert dune.

All simulations in this study were performed in two-dimensions. This approach was used because in three-dimensions, accurate representation of the change in the slope at the crest of the foredune in the mesh proved problematic as it became overly smoothed. In the two-dimensional simulations any change in slope was accurately recreated in the mesh using a polyline. Ideally flow modelling over the foredune would occur in three dimensions as wind is elliptic in nature as demonstrated by Hesp et al. (2015) who confirmed that incident winds which approach obliquely to the dune toe are deflected toward a more crest-normal orientation across the stoss slope of the foredune.

A mesh independence test was performed by calculating wind flow over 3 meshes of 0.5 m, 0.375 m and 0.25 m resolution. Between each case, wind flow at 30 points between 0.1 m and 3 m above the crest of the foredune changed by <1%. Due to the increased resolution of data points, the 0.25 m horizontal resolution mesh was employed for this study. The horizontal extent of each mesh ranged from 156 m for the 0° transect to 199 m for the 70° transect. In all cases the horizontal resolution of the mesh was 0.25 m and the vertical resolution progressed from 0.1 m at the surface to 1.63 m at the upper boundary located 64 m above the beach surface. Vertical cell size resolution of the mesh was restricted by the maximum dune surface roughness height ( $z_0$ ) of 0.05 m. Each simulation was deemed complete when the residuals for each variable being solved (velocity, pressure, turbulent kinetic energy and energy dissipation) decreased by 4 orders of magnitude.

### 2.2.1 Computational Boundary conditions

In each simulation vertical profiles of wind speed ( $U$ ), turbulent kinetic energy ( $k$ ) and energy dissipation ( $\varepsilon$ ) at the inlet boundary were defined assuming a constant shear velocity ( $u_*$ ) value with height using equations 1, 2 and 3 (Richards and Hoxey, 1993 and Blocken et al., 2006):

$$U(z) = \frac{u_*}{k} \ln \left( \frac{z+z_0}{z_0} \right) \quad (1)$$

$$\kappa(z) = \frac{u_*}{\sqrt{C_\mu}} \quad (2)$$

$$\varepsilon(z) = \frac{u_*^3}{k(z+z_0)} \quad (3)$$

Where  $z$  is the height above the surface,  $k$  is the von Karman constant (0.42),  $z_0$  is the surface roughness length and  $C_\mu$  a constant of 0.09.

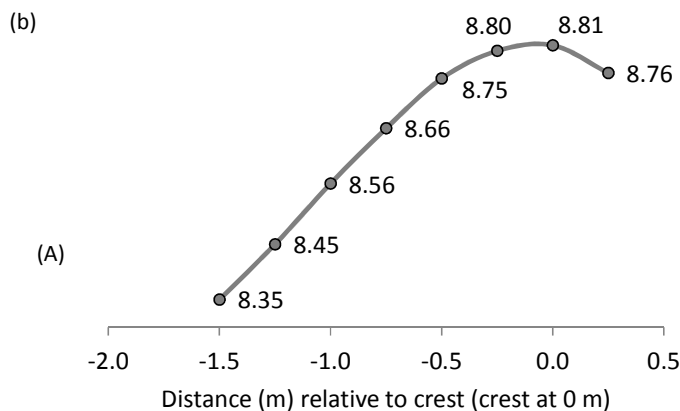

To examine how flow dynamics changed with wind speed, simulations were conducted using 4 values of  $u_*$  ranging from a minimum of  $0.24 \text{ m s}^{-1}$  to  $0.60 \text{ m s}^{-1}$  (Table 1). For each simulation a surface surrounding the dune was prescribed a surface roughness constant ( $z_0$ ) of  $0.0005 \text{ m}$ , the equivalent of a sand surface (Bagnold, 1960). To test how jet dynamics change with roughness height, the foredune was prescribed roughness heights equivalent to that of bare sand ( $z_0$   $0.0005 \text{ m}$  (Bagnold, 1954)), *Ammophila breviligulata* ( $z_0$   $0.01 \text{ m}$  (Olson, 1958)), and thin grass  $0.5 \text{ m}$  high ( $z_0$   $0.05 \text{ m}$  (Sutton, 1953)).

Table 1. Shear velocities ( $\text{m s}^{-1}$ ) and equivalent wind speeds ( $\text{m s}^{-1}$ ) at  $1 \text{ m}$  above the surface at the inlet of the computational domain for each simulation assuming a  $z_0$  of  $0.0005 \text{ m}$ .

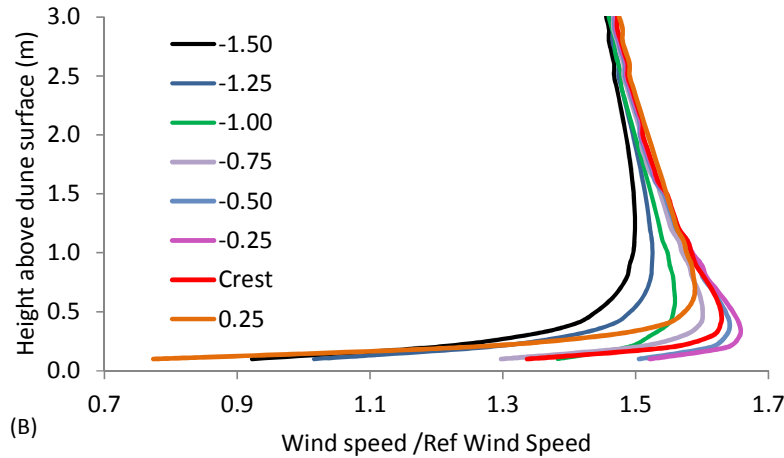

Shear Velocity ( $\text{m s}^{-1}$ )	Wind Speed $4 \text{ m}$ above surface ( $\text{m s}^{-1}$ )
0.23	5.0
0.35	7.5
0.47	10
0.58	12.5

### 3. Location of the Jet Formation

Because it is often the case that there are not enough instrumented masts in the field to adequately cover a foredune, it cannot be determined exactly where on the stoss face or near-crest region the jet flow is first formed. Thus, the CFD model was utilized to examine where the jet first forms on the foredune. Figure 2 illustrates seven locations across the upper stoss, crest and lee slope where velocity profiles were modelled in order to examine the first point of jet formation, and its downwind extension past the crest (if it occurs).

**Figure 2a.** Location of the seven points on the upper stoss slope, crest and lee slope sampled for CFD velocity profiles. The vertical height (m) of each location is labelled. Distance indicated by the x axis is relative to the dune crest (at 0 m).

**Figure 2b.** Wind velocity profiles from the upper stoss slope starting at  $-1.5\text{m}$  upwind (down-slope) of the crest (the red line, at  $0\text{m}$ ) (locations in 2a) and down the upper lee slope for a  $0^\circ$  incident wind (i.e. perpendicular to the dune crest). The velocity profiles indicate progressive acceleration up the stoss slope and the jet flow appears at  $\sim 1\text{m}$  seawards of the dune crest. Ref wind speed refers to wind speed  $4\text{m}$  above the surface at the inlet.

In order to assess this, the wind velocity profiles were modelled at intervals of  $0.25\text{m}$  across the P.E.I. foredune from upper stoss position over the crest, and down the lee slope to determine where the jet flow structure was initiated (Figure 2a). The transect utilized was the scarp profile, and a roughness height equivalent to *Ammophila breviligulata* ( $z_0 0.01\text{m}$ ) was applied to the foredune slope. Figure 2b demonstrates that the flow progressively accelerates up the stoss slope as observed in many similar dune and ridge studies (e.g. Arens et al., 1995; Finnigan, 2007; Walker et al., 2006, 2009; Bauer et al., 2013; Hesp et al., 2009, 2015). While there is some slight indication of jet formation at  $-1.5\text{m}$ , a clear jet is formed at  $1.0\text{m}$  seawards of the crest. The flow becomes better defined as a more pronounced speed bulge (or nose) develops at around  $50\text{cm}$  above the bed at  $-0.75$  to  $-0.5\text{m}$  in the next  $50\text{cm}$  horizontal distance downwind (or upslope), and is most pronounced at  $0.25\text{m}$  seawards or downslope of the crest (Figure 2b). Note that the crest is itself quite convex and rounded (Figure 2a). The jet shifts upwards (to around  $0.75\text{m}$  above the surface) and becomes more bulbous in the profile at  $0.25\text{m}$  past the crest. It is likely that the very top of the crest is the point at which lee flow separation begins, and as this develops, the higher speed jet

1  
2  
3  
4  
5  
6  
7 component of the flow is forced upwards over the separation envelope as observed in other  
8 studies (cf. Hsu, 1977). In addition, the flow tends to sweep upwards across the crest  
9 directed by the steep angle of the stoss slope, so the jet will tend to move upwards in the  
10 profile as it crosses the dune crest. Flow velocities are low near the surface in the lee of the  
11 dune crest due to flow separation development in this region.

12  
13  
14 The wind velocity profile with embedded jet at the dune crest displays a similar structure to  
15 that encountered in the field at P.E.I. (Hesp et al., 2009, 2013), and provides partial validation  
16 of the modelling. The vertical height above the bed at which the jet is most pronounced (the  
17 apex of the nose) in the modelling is lower by approximately 50cm (at the crest) to 25cm  
18 (just downwind of the crest) than that encountered in the field. This is likely due to the  
19 presence of vegetation in the field, whereas there is no vegetation present on the modelled  
20 surface.

#### 21 22 23 24 25 **4. Jet Structure and Incident Wind Speed**

26  
27 As noted in the introduction, observations of jets formed during different incident wind  
28 speeds have been made (e.g. Hsu, 1977; Arens et al., 1995; Hesp et al., 2009, 2013), but it  
29 is unclear if variations in incident wind speed actually produce changes in the jet formation or  
30 shape. Figure 3 shows wind velocity profiles simulated via CFD for four quite different  
31 incident wind velocities ( $5 \text{ m s}^{-1}$  to  $12.5 \text{ m s}^{-1}$  at 4m above the surface on the beach) for a  
32 directly onshore flow.

**Figure 3.** Percent wind velocity profiles at the crest of the foredune for a directly onshore flow. Jets were produced for a range of shear velocities ( $u_*$  0.23 – 0.58) equivalent to incident wind speeds of 5.0 to 12.5  $\text{ms}^{-1}$  at 4 m height on the beach upwind of the foredune. Ref wind speed refers to wind speed 4 m above the surface at the inlet.

Jet flow was produced at the foredune crest for all four wind speeds tested (Figure 3) thereby indicating that once the flow velocity is above the threshold for sand transport, wind speed is not a factor determining whether a jet is present or not. Whilst it superficially appears as if the jet becomes more pronounced as wind speed increases (as in Hesp et al., 2013, their Figure 6)), when the results are made relative to the incident wind speed on the beach (at 4 m height), all the four percent velocity profiles in Figure 3 virtually overlap, and there is only a very slight difference apparent indicating that incident wind speed has minimal effect on jet development.

### 5. Jet Development and Incident Wind Direction

Field observations of jets (e.g. Hesp et al., 2013) indicates that the jets vary according to incident wind direction. In order to test the influence of incident wind direction on jet development, a range of incident wind approach angles from 10° to 70° (almost perpendicular to almost dune crest parallel) were examined via the CFD model (Figure 4). Figure 1 illustrates the 2-D topographic profiles for the range of incident winds modelled. These show

the relative slopes that the incident wind would encounter or “see” as it crosses the dune. Note how the slopes flatten considerably and elongate as the incident wind flow becomes increasingly oblique to the dune crest.

**Figure 4.** Comparison of the foredune crest percent wind velocity profiles for a range of incident wind directions. Zero ( $0^\circ$ ) indicates directly onshore winds. Jet development is not present at an incident approach direction of  $60^\circ$  but is present by  $50^\circ$ , and is most pronounced for onshore to low angle oblique winds. Ref wind speed refers to wind speed 4 m above the surface at the inlet.

The incident wind angle/stoss slope has a significant impact on the production of a jet at the crest. As the incident angle becomes more oblique, making the slope less steep, the jet becomes slower and less defined until it is not discernable past  $50^\circ$  incident wind approach angle (Figure 4). In the field Hesp et al. (2013) found that a jet did not develop when the incident wind was from an angle  $>55^\circ$ .

In three dimensions, the flow is topographically steered before reaching the dune crest (Walker et al., 2006; Hesp et al., 2015). This may cause the jet to form at more oblique incident angles than has been found here.

The jet is also more pronounced (i.e. more defined nose) in the vertical profile during winds that are perpendicular to the crest, likely because the stoss slope is steepest for these incident winds, and perhaps because of the presence of a more defined separation zone, which starts to limit the near surface wind speed near or at the crest.

Wind speed at the crest also decreases as incident wind direction becomes more oblique (cf. Walker et al., 2009; Hesp et al., 2015). The degree and magnitude of jet development for three incident directions (0°, 40° and 70°) may be seen in Figure 5. The red zone indicates a high speed jet zone or region, and this is most pronounced in perpendicular flows. As the dune profile flattens and lengthens and the wind becomes increasingly oblique and the dune profile flattens and lengthens, the red zone decreases in size and the velocity declines. The degree of speedup also decreases as the incident flow becomes more oblique as indicated by the speed zones in Figure 5.

**Figure 5.** The degree and magnitude of jet development for three incident directions (0° - directly onshore, 40° and 70°). The jet is most pronounced and has the greatest aerial extent when winds are perpendicular to the foredune crest.

Figure 6 displays the maximum jet velocity developed at the foredune crest for each incident wind direction (Figure 6a), and the percent jet velocity relative to winds at 3m above the dune crest (Figure 6b). Figure 6c illustrates the log regressions of the vertical profiles of wind velocity up to 3 m height, and shows that as the incident wind becomes more oblique, the

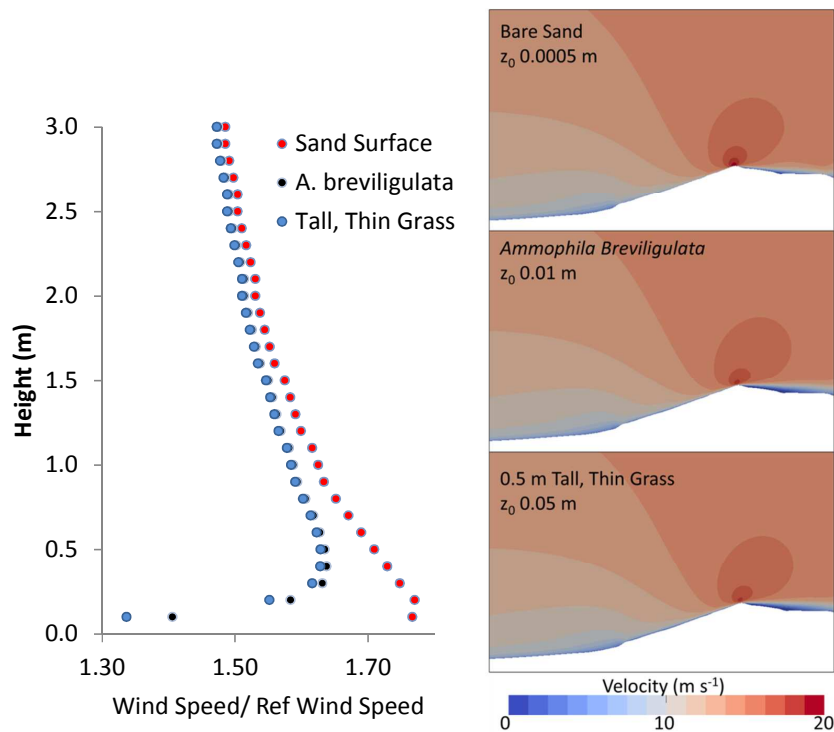

profile becomes more logarithmic. There are clear relationships between these such that the maximum jet speed declines as the incident wind direction becomes more oblique to highly oblique, relative jet velocities are highest compared to flow at 3 m above the foredune crest for directly onshore flow, and the velocity profiles progressively deviate from logarithmic as the incident flow becomes less oblique. The latter has clear implications for those wishing to determine shear stress at the bed from velocity profiles where jets are present. All plots have very high  $R^2$  values.

**Figure 6.** Maximum jet velocity developed at the foredune crest for each incident wind direction (a), the percent jet velocity relative to winds at 3m above the dune crest (b) and the log regressions of the vertical profiles of wind velocity up to 3 m height (c).

## 6. Jet development for varying surface roughness

Figure 7 displays jet development for three surface roughness lengths based on data provided by Maun (2009) and for the same incident onshore wind velocity. It is apparent that the greatest jet development occurs for a bare sand surface with a very low roughness, and decreases with the presence of vegetation. However, there is little difference between a cover of *Ammophila Breviligulata* and thick grass (as defined by Maun, (2009)).

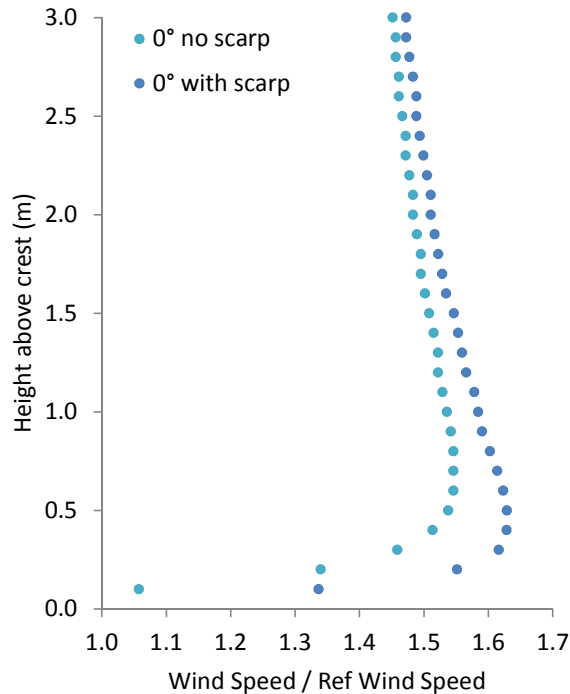

**Figure 7.** Jet development for three different surface roughness lengths. The presence of vegetation retards the degree of jet development. Ref wind speed refers to wind speed 4 m above the surface at the inlet.

### 7. Scarped versus non-scarped foredune topography and jet development

Scarps are very commonly formed on foredunes since they occupy the seaward most position on the backshore (Carter et al., 1990; Hesp, 2002; Christiansen and Davidson-Arnott, 2004). In the discussion above, the CFD modelling (and previous field work) was conducted over the P.E.I. foredune which exhibited a small 0.7m high scarp. Since it is also common for jets to be formed over the crest of such scarps (Bowen and Lindley, 1977; Hesp et al., 2013), the presence of the scarp and attendant jet may have a downwind influence on the development of the foredune crest jet. A 2-D CFD comparison was conducted between the scarped profile and the same profile minus the scarp in order to determine if the scarp has a downwind effect on flow near the crest. Figure 8 demonstrates that the presence of the 0.7m high scarp does indeed influence the structure of the crest jet, in that the jet is more pronounced where the scarp is present. The highest velocities are also slightly closer to the

bed. This may occur due to the scarp jet shedding higher velocity and more turbulent eddies downwind up the foredune stoss face compared to the situation where the scarp is not present.

**Figure 8.** Wind velocity profiles measured at the foredune crest for an onshore 2-D flow for the scarped (0.7m high) and non-scarped morphology. The jet is marginally faster (5%) at the crest where the scarp is present. — Ref wind speed refers to wind speed 4 m above the surface at the inlet.

The presence of the scarp at the dune toe leads to slightly greater development of the jet on the foredune ridge crest. The pressure fields were also examined for this comparison and show that (i) the high pressure zone which develops over the scarp region does not extend as far downwind across the foredune lower stoss slope compared to the non-scarped foredune, and, (ii) the low pressure zone over the dune crest is much higher (25%) for the scarped dune compared to the non-scarped dune.

## 8. Conclusions

The following conclusions can be derived from this study:

1. CFD modelling has successfully replicated jet flow development at a foredune crest region;
2. an increase in incident wind velocity does not affect the magnitude of jet flow;
3. a jet is first formed at ~1.0 m seawards of the foredune crest on the Prince Edward Island foredune morphology example examined here. The flow becomes better defined as a more pronounced nose develops at around 50 cm above the bed upslope, and is best developed at 0.25 m seawards of the dune crest. The jet shifts upwards and becomes slightly more bulbous in the profile just landwards or past the foredune crest and then disappears;
4. the jet is most pronounced and has the greatest aerial extent when winds are perpendicular to the foredune crest;
5. in the CFD modelling a jet did not develop a few degrees after an incident wind approach angle of 50° because there is significantly less flow acceleration across a much lower slope at an incident wind greater than ~55°;
6. the jet is higher in the vertical profile during winds that are more perpendicular to the dune crest in the 0° to 30° range of incident winds;
7. the degree of surface roughness influences the degree of jet development such that jets are better developed when the surface is bare compared to when vegetation is present;
8. the presence of a scarp at the dune toe does slightly influence the structure of the crest jet, in that the jet is more pronounced where a scarp is present.
9. jets are probably more common over dunes and similar topographies than believed or found due to (i) post data collection smoothing of velocity profiles (cf. Frank and Kocurek, 1996), or (ii) the fact that many field based wind profiling experiments do not have enough instruments stacked at closely spaced heights above the surface to be able to detect their presence.

3  
4  
5  
6  
7 Future research aims to examine the relationships between foredune morphology (particularly  
8 height and stoss slope gradient) and jet development, the nature of jet breakdown or  
9 dispersion, the nature of secondary circulation and instabilities in jets (see e.g. Ruith et al  
10 2003; Cala et al 2006), and the dynamics and relationships between jet flow and reversing  
11 vortices within flow separation envelopes at, and past the foredune crest.

Figure 4. Comparison of the foredune crest percent wind velocity profiles for a range of incident wind directions. Zero ( $0^\circ$ ) indicates directly onshore winds. Jet development is not present at an incident approach direction of  $60^\circ$  but is present by  $50^\circ$ , and is most pronounced for onshore to low angle oblique winds. Ref wind speed refers to wind speed 4 m above the surface at the inlet.  
136x104mm (150 x 150 DPI)

view

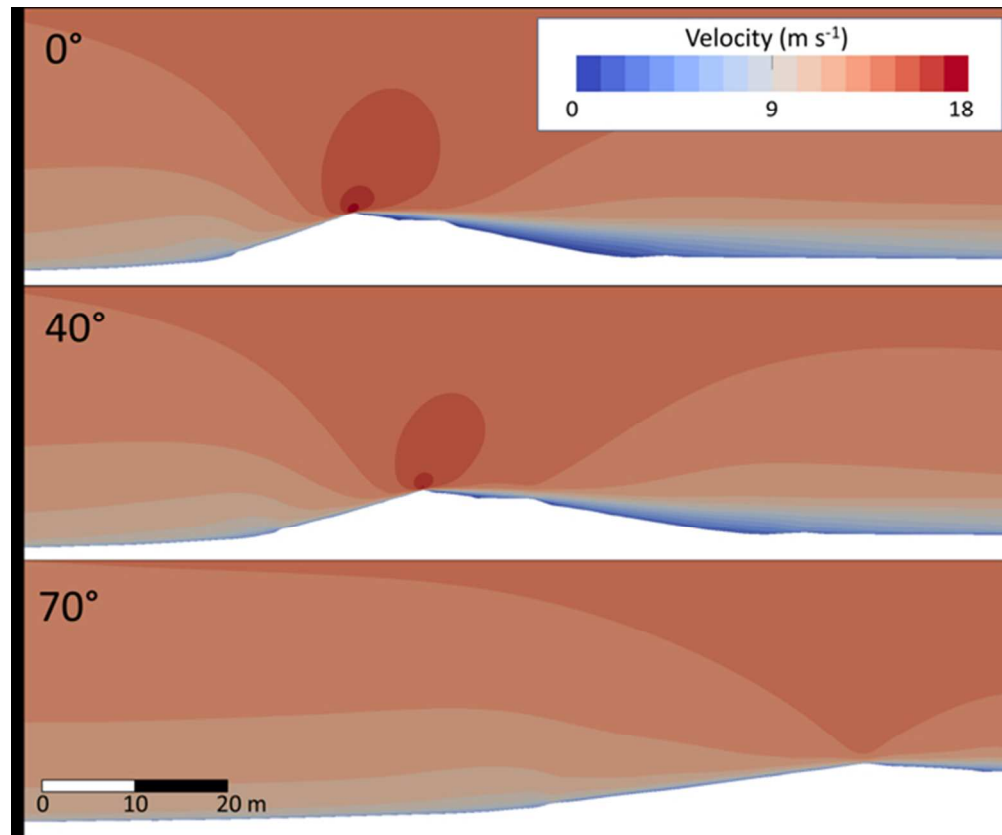

Figure 5. The degree and magnitude of jet development for three incident directions (0° - directly onshore, 40° and 70°). The jet is most pronounced and has the greatest aerial extent when winds are perpendicular to the foredune crest.  
116x96mm (150 x 150 DPI)
